

Gold Sterilization and the Recession of 1937-38

Douglas A. Irwin
Dartmouth College and NBER

This Draft: September 9, 2011

Abstract:

The Recession of 1937-38 is often cited as illustrating the dangers of withdrawing fiscal and monetary stimulus too early in a weak recovery. Yet existing studies of the recession find that changes in fiscal policy were small in comparison to the magnitude of the downturn, and that higher reserve requirements were not binding on banks. This paper focuses on a neglected change in monetary policy, the sterilization of gold inflows during 1937, and finds that it exerted a powerful contractionary force during this period.

Introduction

The Recession of 1937-38 was America's third most severe economic downturn in the twentieth century, after 1929-33 and 1920-21. Real GDP contracted 11 percent and industrial production plunged 30 percent between the second quarter of 1937 and the first quarter of 1938. The civilian unemployment rate, still high in the aftermath of the Great Depression, rose from 9.2 percent to 12.5 percent. Because this sharp downturn occurred when recovery from the Depression was far from complete, it became known as the "recession within a depression." It set back the recovery from the Depression by two years.

The recession is often blamed on the tightening of fiscal and monetary policies. In terms of fiscal policy, the Roosevelt administration became concerned about large budget deficits and began reducing the growth in government spending and increasing taxes.¹ In terms of monetary policy, the Federal Reserve and Treasury became concerned about the inflationary potential of

¹ Much of the reduction in spending was simply the ending of the veteran's bonus. In 1936, over President Roosevelt's veto, Congress enacted a large bonus for veterans that was distributed in June 1936 and again (by half as much) in June 1937 and then not at all in 1938. Furthermore, in January 1937, the government began collecting social security taxes (without equivalent payouts) and undistributed profits tax, but the amounts collected were relatively small.

excess reserves in the banking system and large gold inflows, and therefore decided to double reserve requirements and sterilize gold inflows.

Yet the evidence that these policy changes were responsible for a downturn of the magnitude seen is underwhelming. Although Brown (1956) finds that the fiscal contraction amounted to a swing in demand of 2.5 percent of GDP in 1938, Romer (1992, 766) finds a relatively small fiscal multiplier during this period and argues that “it would be very difficult” to attribute most of the decline in output to fiscal policy.² And while Friedman and Schwartz (1963) put great emphasis on the contractionary impact of higher reserve requirements, subsequent studies have found little support for this conclusion, including Cole and Ohanian (1999), Telser (2001-02), Stauffer (2002), Hanes (2006), and Calomiris, Mason, and Wheelock (2011). For example, Calomiris, Mason, and Wheelock (2011) report that the reserve requirements were not binding on banks, which held large excess reserves at the time, and that the banks did not increase their demand for reserves after the new requirement took effect. Therefore, it appears that the reserve requirements had little if any effect on the money multiplier and the supply of money and credit.³

If these factors cannot be blamed for the severity of the recession, might the big “policy mistake” of the period have been the sterilization of gold inflows?⁴ Unfortunately, the quantitative significance of the gold sterilization policy has never been fully assessed. Friedman and Schwartz (1963, 544) maintained that “The combined impact of the rise in reserve

² Peppers (1973) later increased the Brown estimate to 3.4 percent of GDP.

³ Telser (2001-02) argues that business loans continued to increase after the reserve requirement increase, and in fact were much greater in the second half of 1937 than in the second half of 1936. Hanes (2006) finds no evidence that the higher reserve requirements affected interest rates.

⁴ There could have been other factors behind the recession. Eggertsson and Pugsley (2006) develop a dynamic stochastic general equilibrium model with sticky prices and rational expectations and argue that the recession was due to an “exogenous shift in beliefs” about future policy by policymakers, i.e., statements by policymakers reflecting concern about inflation. Yet it seems implausible to think that “animal spirits” could sink the economy as much as occurred during 1937-38 in the absence of some tangible change in government policy or some real shock.

requirements and – no less important – the Treasury gold-sterilization program first sharply reduced the rate of increase in the monetary stock and then converted it into a decline” (emphasis added).⁵ Yet they did not provide any direct evidence to support this judgment: how do we know that the gold sterilization policy was “no less important” than the change in reserve requirements?

Though understudied by economists, the decision by the Treasury Department to sterilize gold inflows from December 1936 until February 1938 turns out to have been a very large monetary shock. By preventing gold inflows from becoming part of the monetary base, this policy brought to an abrupt halt to what had been a strong monetary expansion. After growing at about a 17 percent annual rate from 1934-36, the monetary base ceased expanding in 1937. This shift in policy was potentially important because, as Romer (1992) points out, the inflow of gold from Europe - and the consequent expansion of the monetary base and money supply – was the driving force behind the economic recovery from the Depression. The sterilization policy severed the link between gold inflows and monetary expansion.

This paper aims to quantify the impact of the gold sterilization on the money supply, and to compare it to the monetary impact of the change in reserve requirements. The contributions of each to the decline in the money supply can, in principle, be traced because the Treasury’s policy of gold sterilization operates through the monetary base while the Federal Reserve’s policy of higher reserve requirements operates through the money multiplier.

This paper reports several findings. First, the change in the monetary base as a result of sterilization was large. As much as a 10 percent increase in the monetary base in 1937 was prevented as a consequence of the program. Second, the monetary base was a more important

⁵ In fact, Friedman and Schwartz pay relatively little attention to the Treasury decision, while devoting several pages to the change in reserve requirements.

source of change than the money multiplier in leading to the tighter monetary policy in the period going into the recession. Third, the end of the sterilization program and the resumption of large gold inflows coincide with the onset of a strong economic recovery. By contrast, the hike in reserve requirements was only partially rolled back and does not appear to have contributed to the relaxation of monetary conditions. Thus, while the Federal Reserve is often blamed for its poor policy choices during the Great Depression, the Treasury Department was largely responsible for the policy tightening during this period.

Monetary Policy and the Recession

The Roosevelt administration's decision to take the United States off the gold standard in April 1933 was the proximate cause of the end of the Great Depression and the start of the economic recovery (Temin and Wigmore 1990, Eggertsson 2008). By freeing monetary policy from the constraint of maintaining a fixed dollar price of gold, the decision permitted a more expansionary policy that ended the deflation, reduced nominal and real interest rates, allowed the foreign exchange value of the dollar to depreciate, and thereby stimulated the economy.

After a period of monetary instability, the United States fixed the price of gold at \$35 per ounce in January 1934. While this did not constitute a formal return to the gold standard, the United States shadowed the gold standard in that changes in gold reserves were reflected in changes in the monetary base. Monetary policy was completely passive to these changes in gold reserves and the Federal Reserve did not engage in any significant open market operations (Friedman and Schwartz 1963, Meltzer 2003).

The United States also began experiencing large gold inflows starting in 1934, something that is often attributed to the revaluation of gold and political difficulties in Europe. This proved

to be the major source of monetary expansion over the next few years. As Romer (1992) argues, expansionary monetary policy was a critical part of the recovery from the Great Depression.

Real GDP grew 11 percent a year, on average, between 1933 and 1936.

With the economy operating with substantial excess capacity, this monetary expansion did not lead to a problem with inflation. Wholesale prices were virtually unchanged during 1935 and into the first half of 1936. However, while consumer prices remained steady, wholesale prices began to rise briskly in the second half of 1936. By December of that year, they were 4 percent higher than they had been a year before. Meanwhile, gold continued to pour in from abroad and banks continued to accumulate large excess reserves, which Treasury and Federal Reserve officials viewed as an increasing risk of inflation.

With prices beginning to accelerate and gold inflows contributing to a rising stock market, President Roosevelt also became concerned about overheating, even though unemployment remained quite high. The president wanted to reduce speculative capital inflows – “hot money,” he called it – without reducing domestic investment (Meltzer 2003, 505). The debate over the proper response led to a dispute between Treasury Secretary Henry Morgenthau and Federal Reserve Chairman Marriner Eccles. Eccles favored increases in reserve requirements, which Morgenthau opposed for fear that it would reduce bank lending. Morgenthau advocated sterilizing gold inflows, while Eccles equivocated.⁶

Eventually, both policies were adopted. Without informing the Treasury, the Federal Reserve increased reserve requirements for member banks from 13 percent to 19.5 percent in August 1936. In December 1936 the Treasury announced that it would begin sterilizing all changes to U.S. gold reserves, arising from gold inflows and domestic production. In January

⁶ Eccles eventually supported the Treasury plan, with reservations because it made Treasury a major player in terms of monetary policy. President Roosevelt ordered the program to begin. Meltzer (2003, 506ff) provides a good overview of the debate.

1937, the Federal Reserve announced that reserve requirements would be further increased in March and May of that year, to 22.75 percent and then to 26 percent. Thus, between August 1936 and May 1937, reserve requirements for member banks were doubled.

The U.S. economy reached a business cycle peak in mid-1937.⁷ As late as June 1937, the Federal Open Market Committee still viewed gold inflows as the most important problem that it faced. It was also concerned that the Treasury might end its sterilization program (Meltzer 2003, 523). In September, industrial production began to plummet. Also that month, the Federal Reserve asked the Treasury to de-sterilize \$300 million to meet seasonal demand for currency, not to address the economic downturn. By October, after a stock market crash and further bad economic news, government officials began to realize that they had a major contraction on their hands.

Policymakers were slow to respond to the sharp downturn in the economy. In February 1938, well into the recession, the Treasury announced that it would no longer sterilize changes in gold reserves unless the change exceeded \$100 million in any quarter. In April, President Roosevelt officially terminated the sterilization program and the Treasury began to de-sterilize the balance of gold in the inactive fund. (The next section describes how the sterilization worked.) The president also announced that the Federal Reserve would roll back the last increase in reserve requirements, reducing them from 26 percent to 22.75 percent.

In June 1938, the trough of the downturn was reached, according to both the NBER and Romer (1994). Thereafter, the economy began a swift recovery. Gold inflows surged in the fall as European fears of war spread due to the crisis over Hitler's territorial demands on Czechoslovakia.

⁷ The business cycle peak was either in May (according to the NBER) or August (according to Romer 1994).

Treasury's Gold Sterilization Program

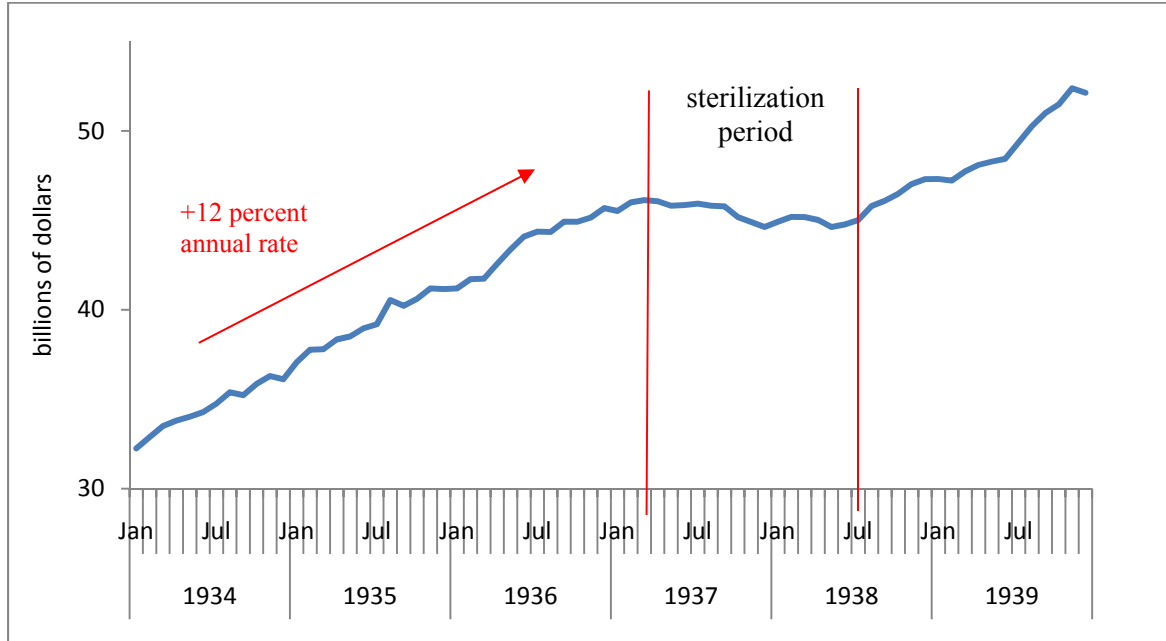

As noted earlier, fiscal policy is generally believed to have been a contributing factor to the recession of 1937-38, but one that is far from being able to explain the severity of the downturn. However, that the U.S. economy was hit by a pronounced monetary shock is beyond dispute.⁸

As Figure 1 shows, the M2 measure of the money supply grew at a fairly consistent 12 percent annual rate between 1934 and 1936. In early 1937, it abruptly ceased growing and actually declined by the end of the year. As noted earlier, economists have failed to uncover convincing evidence that the doubling of reserve requirements was responsible for this shift. Because banks held large excess reserves, the increased reserve requirements were not binding and do not appear to have constrained bank lending (Calomiris, Mason, and Wheelock 2011). Furthermore, banks did not seek to build up their excess reserves to their previous level. This leaves the gold sterilization policy as the potentially important monetary factor in the downturn, but one whose quantitative significance has never been fully explored.⁹

⁸ Velde (2009) used a VAR model and found that monetary shocks dominated fiscal shocks in the recession of 1937-38, but he did not separate the impact of the gold sterilization program from the doubling of reserve requirements.

⁹ The sterilization program was undertaken by the Treasury Department, not the Federal Reserve, which may explain why it has not received the attention it deserves.

Figure 1: The U.S. Money Supply (M2), 1934-1939

Source: Friedman and Schwartz (1970), Table 1, column 9.

How did the sterilization policy work? The Treasury Department purchased all gold inflows at \$35 per ounce with drafts from its balance at the Federal Reserve. Normally, it would print gold certificates for the equivalent amount and deposit them in a Federal Reserve account to replenish its balance. The certificate would then become part of the monetary base and could be used to increase bank reserves. However, with sterilization, instead of replacing its withdrawn balance with a gold certificate in equal amount, the Treasury kept the certificates in an “inactive” account where it could not be used for the expansion of credit. It paid for the gold out of its general fund, reducing its balances at the Federal Reserve, which would then have to be replenished by issuing new debt or raising tax revenue.

Figure 2 shows monthly data on the changes in the gold stock (largely driven by gold inflows from abroad) and the offsetting Treasury action. The program began at the end of

December 1936. From January through August 1937, the Treasury offset dollar-for-dollar any increase in its gold holdings. In Figure 2, this policy is reflected in a bar of equal and opposite sign to the change in gold holdings. In September 1937, at the request of the Federal Reserve, the Treasury desterilized \$300 million. It resumed sterilization in October.

By this time, the U.S. economy was clearly in a recession, and financial markets became suspicious that the Roosevelt administration might consider a devaluation of the dollar (an increase in the dollar price of gold) to deal with the recession. (After all, this is exactly how the Roosevelt administration dealt with the Great Depression when it took office, so there was clearly a precedent for such an action.) As a result, gold inflows into the United States came to a halt. From November 1937 through January 1938, the United States actually lost a small amount of gold, and sterilization worked in reverse: the loss of gold did not translate into a reduction in the monetary base because it was offset by the Treasury's release of gold from its inactive account.

The sterilization program was effectively ended in February 1938, when the Treasury announced that it would no longer sterilize changes in gold reserves that were less than \$100 million. In February and March 1938, gold inflows were extremely small and were not sterilized.

The Treasury program was formally terminated in April. The Treasury then shifted about \$1.3 billion from its cash holdings to deposits in Federal Reserve banks. However, this was just an accounting change with no monetary effect; it was not until the Treasury spent the funds that they were actually monetized.¹⁰ The Treasury's exit strategy was to desterilize its inactive gold

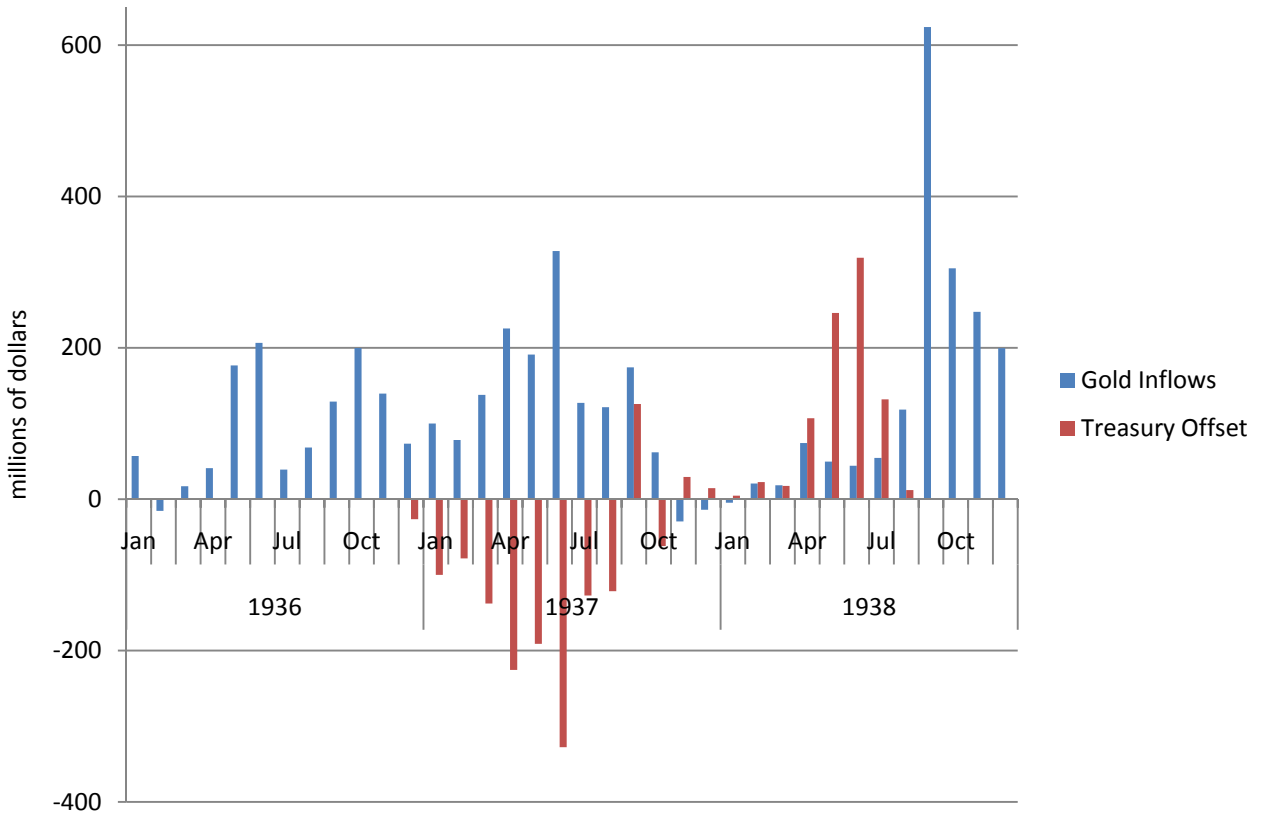

¹⁰ As Friedman and Schwartz (1963, 511) note: "Initially, the impact gold was simply moved from Treasury cash to Treasury deposits at Federal Reserve Banks, and so had no immediate monetary effect. Effective desterilization did not occur until more than a year after formal desterilization." Similarly, the Federal Reserve noted "as the result of the release of gold, funds in the amount of about \$1,400,000,000 were added to Treasury deposits at the Federal

holdings gradually, although nearly half of the inactive gold was monetized within a month and a half, that is, \$670 million from mid-April to the end of June (Federal Reserve Bulletin, July 1938, 557).

The release of the inactive gold allowed growth in the monetary base to resume. But fears that the Roosevelt administration might address the recession by devaluing the dollar meant that gold was not flowing back to the United States. Once the inactive gold had been fully desterilized, the monetary base would stop growing again in the absence of gold inflows. In June, President Roosevelt and Treasury Secretary Morgenthau firmly denied that they had any plans to devalue the dollar. Still, gold inflows did not resume in significant amounts until the crisis over Czechoslovakia in September led to fears of war and capital flight from Europe.

Reserve banks, and as these funds are expended by the Treasury they will correspondingly increase member bank reserves” (Federal Reserve Bulletin, May 1938, 344).

Figure 2: Change in Gold Holdings and Treasury Sterilization

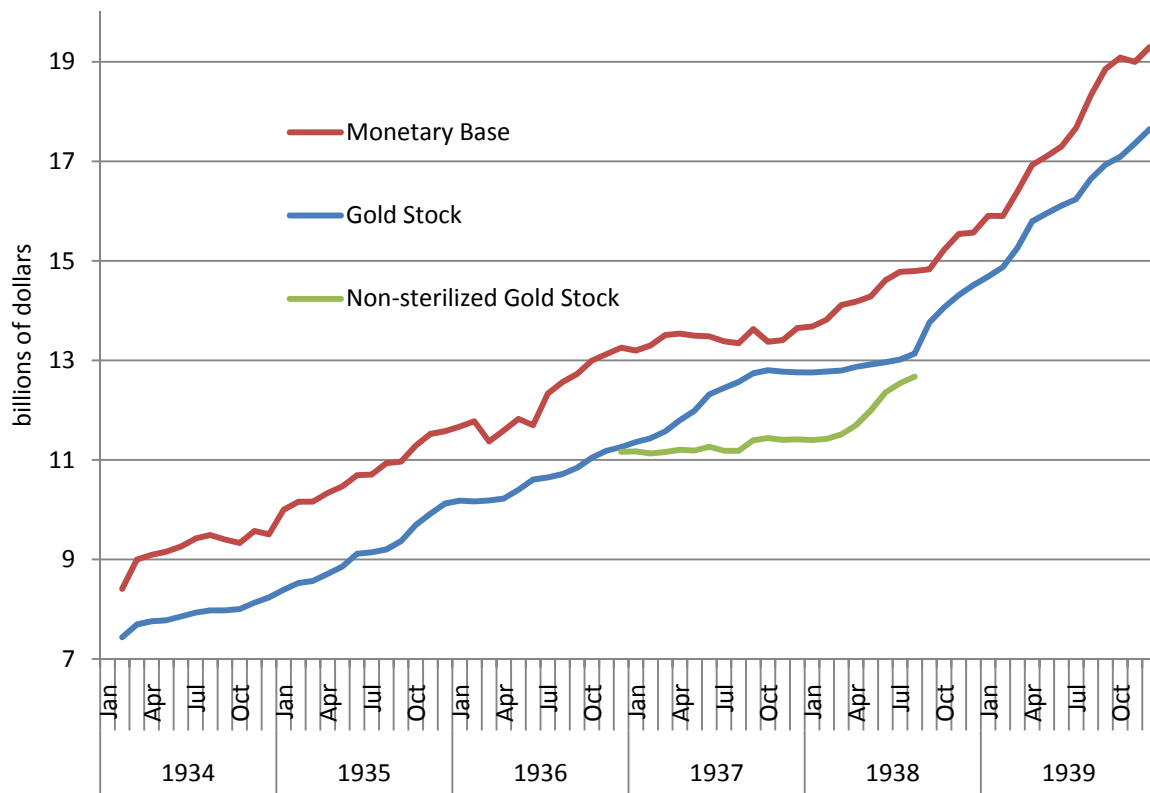

Source: Gold reserves, Board of Governors of the Federal Reserve System (1943), Table 156, p. 537. Treasury offset, *ibid.*, Table 151, p. 515. See also the appendix to this paper.

The magnitude of the sterilization operation was enormous. Between December 1936 and August 1937, the Treasury sterilized all the increase in the domestic gold stock. At its peak, in early September 1937, the Treasury had accumulated \$1.4 billion in inactive gold reserves. This amounts to 10 percent of the monetary base as of December 1936.

The relationship between gold reserves and the monetary base is shown in Figure 3. Gold reserves constituted about 85 percent of the monetary base through this period, and therefore changes in the gold stock usually had a pronounced impact on the monetary base. As the figure shows, the gold stock and the monetary base rose together from 1934 to 1936. The

gold stock continued to increase in 1937, but the increase was sterilized and so the monetary base remained flat. The flat “non-sterilized gold” line shows the amount of monetary gold in the financial system. Then, in late 1937, gold stopped flowing into the country and the country’s gold stock remained largely unchanged.

Figure 3: Gold Stock, Non-sterilized Gold Stock, and Monetary Base

Source: Monetary base: Friedman and Schwartz (1963, Table B-3, column 1). Gold stock: Board of Governors of the Federal Reserve System (1943, Table 156). For sterilization, see the appendix to this paper.

To characterize the relationship between the two variables more formally, consider the following simple regression of the change in the log of the monetary base on the change in the log of the gold stock:

$$\Delta \log (\text{monetary base}_t) = \alpha + \beta \Delta \log (\text{gold stock}_t) + \varepsilon_t$$

There should be a strong relationship between the change in the gold stock and the change in the monetary base between 1934 and 1936, but not after that point if sterilization is not taken into account. The potential for a structural break in the relationship can be tested by including a dummy variable that takes the value of 1 during the sterilization period (December 1936 through January 1938).

The results in Table 1 simply confirm the pattern in Figure 3. Changes in the gold stock explain changes in the monetary base very well, except during the period of sterilization. The coefficient on the interaction between the change in the gold stock and a dummy variable representing the sterilization period is nearly equal and opposite to the sign of the coefficient on the change in the gold stock, reflecting the sterilization offset. By contrast, a measure of the monetized gold stock (adjust for sterilization) shows no structural break during this period.

Table 1: Impact of Changes in Gold Reserves on the Monetary Base

Dependent Variable: change in monetary base

	Gold stock not controlling for sterilization	Gold stock Adjusted for sterilization
Change in gold stock	0.66* (0.21)	0.61* (0.19)
Change in gold stock X sterilization period dummy	-0.82* (0.16)	-0.07 (0.20)
R ²	0.26	0.13

Note: time period: 1934:03-1939:12 (N = 70). Robust standard errors in parentheses. The second regression includes a dummy variable for September 1938, as it is unclear how the small remainder of the sterilized gold was deesterilized.

Furthermore, this equation can be estimated for the period through 1936 and then used to generate an out of sample forecast of the monetary base using actual gold flows. This indicates how the monetary base would have behaved without sterilization, and given actual changes in the gold stock. This confirms the earlier conclusion that, by the fourth quarter of 1937, the monetary base was 10 percent smaller than it would have been had gold not been sterilized.

Such a forecast raises the question of whether the observed inflows in 1937 can be taken as given, or whether they were affected by the sterilization program. One argument would be that the observed gold flows between December 1936 and August 1937 were unaffected by the sterilization program. The increase in the gold stock during the sterilization period was not out of line with that previously observed. Gold inflows grew at a 15 percent average annual rate between 1934 and 1936 and at a 15 percent annual rate in 1937 up to October of that year. The ongoing fears of war in Europe might have ensured the continued flow of gold to the United

States in the absence of the sterilization program. It was only when fears of devaluation emerged that the gold stopped flowing in.

Another argument would be that the sterilization program led to additional gold inflows. Hanes (2006) finds that interest rates rose slightly around the time that the sterilization program was put into operation. This might have attracted gold to the United States that otherwise would not have come. This would make the conclusion that sterilization reduced the monetary base by 10 percent an overestimate.

Alternatively, to the extent that sterilization contributed to the sharp recession in the second half of 1937, and led to fears of a devaluation, it clearly reduced gold inflows into the United States.

Reserve Requirements or Gold Sterilization?

The gold sterilization program and the doubling of reserve requirements occurred at roughly the same time, making it difficult to determine which was most responsible for change in the money supply.¹¹ Yet it is important to know whether the Federal Reserve's decision to increase reserve requirements or the Treasury's decision to sterilize gold inflows was the most important in order to reach conclusions about the role of different economic policies during the 1930s.

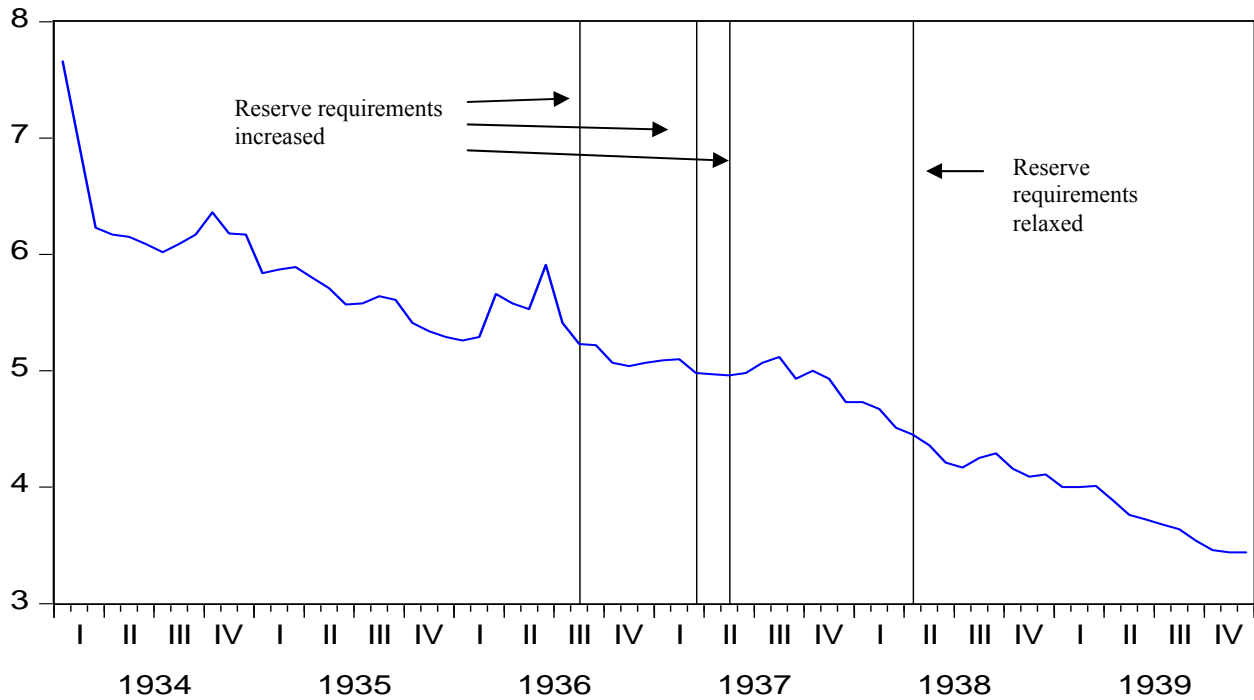

One way the two policies can be disentangled is to note that Treasury's gold sterilization affects the monetary base, whereas the Fed's reserve requirement increases affect the money multiplier (via the deposit-reserve ratio). We have already seen that the sterilization program had a significant impact on the monetary base. Did changes in reserve requirements have a

¹¹ As noted earlier, Velde (2009) used a VAR model and found that monetary shocks dominated fiscal shocks in the recession of 1937-38, but he did not separate the impact of the gold sterilization program from the doubling of reserve requirements.

discernable impact on the deposit-reserve ratio, and hence on the money multiplier and money supply?

Figure 3 shows the path of the deposit-reserve ratio from 1934 to 1939. The first three vertical lines denote the increase in reserve requirements and the last the relaxation of reserve requirements. If the reserve requirement changes had an immediate impact, we would expect to see a drop in the deposit-reserve ratio after an increase in the requirements and a rise in the ratio after a decrease in the requirements. The deposit-reserve ratio declines secularly over this period, but surprisingly, the ratio flattens out during the period when the reserve requirements were increased. Not until the very end of 1937, in December, well after the final increase in reserve requirements and the start of the recession, does the ratio begin to decline, but then only in line with its previous trend decline. This is not consistent with the reserve requirements having a major contractionary impact. In addition, the relaxation of the reserve requirements does not lead to an increase in the deposit-reserve ratio, as we would have expected. This makes it hard to attribute the easing of monetary conditions, that is, the resumption of growth in the money supply in late 1938, to the changes in reserve requirements.

Figure 3: The Deposit-Reserve Ratio, 1934-39

Source: Friedman and Schwartz (1963, Table B-3, column 2).

To distinguish the contributions of sterilization and reserve requirements, in terms of the magnitude and the timing of their impact on the money supply, we can undertake a decomposition in the spirit of Cagan (1965). The money stock (M , measured by $M2$) is equal to

$$M = \frac{H}{\frac{C}{M} + \frac{R}{D} - \frac{C}{M} \frac{R}{D}}$$

where H is high powered money (the monetary base), C is currency in the hands of the public, R is reserves, and D is deposits. The change in the money supply can be decomposed into the changes in these components:

$$\Delta \log(M) = \Delta \log(H) + \frac{M}{H} \left(1 - \frac{R}{D}\right) \Delta \left(-\frac{C}{M}\right) + \frac{M}{H} \left(1 - \frac{C}{M}\right) \Delta \left(-\frac{R}{D}\right)$$

where the first component is the contribution of the monetary base, the second is the change in the currency-money ratio, and the third is the change in the reserve-deposit ratio.

Table 2 presents the results for six key periods. Two pre-sterilization periods are considered, from February 1934 to November 1936, and the shorter six month period May-November 1936. In the two years prior to the sterilization of gold, the gold stock and high powered money (the monetary base) grew at an annual rate of 11.5 percent. Changes in the currency-money ratio were relatively small, but the higher reserve-deposit ratio meant that M2 grew at only about 8 percent. In the six months prior to the implementation of the sterilization program, gold reserves and high powered money increased at an annual rate of roughly 20 percent, but M2 growth was still about 8 percent, held down by an increase in the reserve-deposit ratio.

Over the nine months during which gold inflows were sterilized, from December 1936 to August 1937, the gold stock increased at a 12 percent annual rate, but high powered money and M2 increased at about a 2 percent pace. Yet during this period, the change in the reserve-deposit ratio was negligible, and even supported easier monetary conditions. Thus, the sharp slowdown in the growth of high powered money led to a marked deceleration in the growth of the money supply.

During the gold scarcity period, August 1937 to February 1938, gold inflows largely ceased, so that sterilization made little difference. Gold inflows increased only 4 percent, while the monetary base increased somewhat more because of the one-time desterilization of \$300

million in September 1937. However, an increase in the reserve-deposit ratio offset the increase in high powered money and M2 actually fell.

From February 1938 to August 1938, the Treasury desterilized its gold accumulation, allowing high powered money to increase at nearly a 13 percent annual rate even though gold inflows remained at a low level. However, this was not fully offset by a continued rise in the reserve-deposit ratio and the money supply grew.

Finally, starting in August 1938 and the Czechoslovak crisis in Europe, gold inflows resumed and, with the sterilization program having been abandoned, monetary growth as well. Gold reserves increased at an annual rate of more than 24 percent in the six months after August, allowing high powered money to grow more than 14 percent, with a slight offset coming from the reserve-deposit ratio.

Table 2: Sources of (Annualized) Change in M2

		$\Delta M2$	Sources of change in M2			ΔG
			ΔH	$\Delta(C/M)$	$\Delta(R/D)$	
Presterilization Period	Feb 1934 – Nov 1936	8.2	11.5	+2.2	-4.9	11.5
Presterilization Period	May 1936 – Nov 1936	8.0	20.9	-2.0	-10.1	18.1
Sterilization Period	Nov 1936 - Aug 1937	2.0	2.2	-1.4	1.1	15.7
Gold scarcity period	Aug 1937 – Feb 1938	-2.8	7.0	1.1	-10.0	4.1
Desterilization Period	Feb 1938 - Aug 1938	2.7	13.6	0.9	-10.4	4.5
Post Munich Period	Aug 1938 - Feb 1939	6.1	14.4	-1.4	-6.5	24.7

Figures may not sum to $\Delta M2$ due to approximation error.

Data Sources: M2: Friedman and Schwartz (1970, Table 1, column 9). High powered money: Friedman and Schwartz (1963, Table B-3, column 1). Currency-money ratio: Friedman and Schwartz (1970, Table 1, column 1). Reserve-deposit ratio: Friedman and Schwartz (1963, Table B-3, column 2). Gold reserves: Board of Governors of the Federal Reserve System (1943, Table 156).

There is no doubt that the increase in the reserve-deposit ratio generally acted as a break on monetary expansion during this period. However, the changes in the reserve-deposit ratio are not closely associated with the change in reserve requirements. In the period around the last two increases in requirements, the reserve-deposit ratio is largely unchanged. This is not what we would expect if the changes in reserve requirements were binding on banks and an important determinant of the reserve-deposit ratio. On the other hand, during the November 1936-August 1937 period, to judge by the increase in gold reserves, we would have expected the monetary base to increase about 16 percent. Yet sterilization held it back to about 2 percent. Thus, we would have expected the growth of the money supply to continue at its previous pace instead of declining sharply.

Conclusions

The Recession of 1937-38 is often cited as illustrating the dangers of withdrawing fiscal and monetary stimulus too early in a weak recovery (Romer 2009). This paper focuses on an understudied change in monetary policy, the decision to sterilize gold inflows during 1937. The findings suggest that it was the major “policy mistake” of the period, one that largely stopped the growth of the monetary base in the period leading into the recession. The monetary base had been growing at a 15 percent annual rate in the months prior to sterilization, so the policy contributed to a significant slowdown in the growth rate of the money supply.

This paper has deliberately stopped short of examining the impact of these monetary changes on the real economy. Economists who have studied the 1930s have broadly concluded that the monetary shocks of the period were an important feature of fluctuations in real economic activity (Romer and Romer 1989, McCallum 1990, Romer 1992, Bordo, Choudhri, and Schwartz

1995, Velde 2009). Thus, it does not seem unreasonable to conclude that the policy succeeded in squelching incipient inflationary pressures, but at the cost of a major recession. When the sterilization program was abandoned, growth in the money supply resumed and the economy began to recover.
